1. Introduction

Strong attractive interactions between the $\eta$ meson and nucleons mean that there is a chance to form $\eta$ meson bound states in nuclei [1]. If discovered in experiments, these mesic nuclei would be a new state of matter bound just by the strong interaction without electromagnetic Coulomb effects playing a role. Strong interaction bound states are formed in a different way as compared to exotic atoms which involve binding of electrically charged mesons with nuclei. For the latter, negatively charged pions or kaons could replace an electron in an outer orbital in a standard atom and get bound in the atom due to the Coulomb interaction. The charged meson in such an excited state quickly undergoes transitions to the lower states until it is close enough to the nucleus and is either absorbed by the nucleus or lost in a nuclear reaction. For strong interactions, in contrast to the pion, the neutral $\eta$ meson is special due to the strong attractive nature of this meson-nucleon interaction [1]. An off-shell $\eta$ meson produced in nuclear reactions such as the $pd \rightarrow ^3\text{He}$ and $pd \rightarrow ^3\text{He}$ below the $\eta$ production threshold may form a bound state with the nucleus within which it is produced. Thus the absence of the electromagnetic interaction and the attractive nature of the $\eta$-nucleon interaction, makes the case of the neutral $\eta$ meson different from that of the pion or the kaon and opens the possibility for an exotic nucleon made up of the meson and nucleons. Early experiments with low statistics using photon [2,3], pion [4], proton [5] or deuteron [6–9] beams gave hints for possible $\eta$ mesonic bound states but no clear signal [10,11].

Here we present a new high statistics search for $^3\text{He}-\eta$ bound states with data from the WASA-at-COSY experiment. We focus on the two main neutral decay channels of the $\eta$ meson: $\eta \rightarrow 2\gamma$ with branching ratio $39.41 \pm 0.20\%$ and $\eta \rightarrow 3\pi^0 \rightarrow 6\gamma$ with branching ratio $31.54 \pm 0.22\%$ [12]. These processes constitute more than 70% of the $\eta$ decays. The choice of neutral decay channels minimizes final state interactions involving charged particles. Concurrent measurement of the two channels increases the statistics and enables one to control systematic uncertainties in photons detection. The two-photon decay was previously suggested in [13] as a clean probe of the $\eta$ in nuclear media.

Considering the $\eta$-nucleus interaction, bound states can be formed by the attractive interaction with finite level width corresponding to the finite lifetime of the state due to the absorptive interaction with the nucleus. The momentum distribution of the bound $\eta$ meson determines the sum of the momenta of the emitted photons. Nuclear absorption and the additional $\eta$ decay (disappearance) processes, reduces significantly the in-medium branching ratio of $2\gamma$ and $6\gamma$ decay channels [14].

$\eta$ meson interactions with nucleons and nuclei are a topic of great experimental and theoretical interest. For recent reviews see [10,11,15–17]. Possible $\eta$-nucleus binding energies are related to the $\eta$-nucleon optical potential and to the value of $\eta$-nucleon scattering length $a_{\eta N}$ [18]. Phenomenological estimates for the real part of $a_{\eta N}$ are typically between 0.2 and 1 fm depending on the model assumptions. $\eta$ bound states in helium require a large $\eta$-nucleon scattering length with real part greater than about 0.7–1.1 fm [19–21]. Recent calculations in the framework of optical potential [22], multi-body calculations [20], and pionless effective field theory [19] suggest a possible $^3\text{He}-\eta$ bound state.

Modifications of meson properties are expected in medium. In studies of the transparency of nuclei to propagating mesons produced in photoproduction experiments one finds strong $\eta$ absorption in nuclei [24]. For the $\eta'$ one finds weaker interaction with the nucleus. An effective mass shift for the $\eta'$ in medium has been observed by the CBELSA/TAPS Collaboration [25]. The $\eta'$-nucleus optical potential $V_{\eta'} = V_{\text{had}} + V_{\text{m}}$ deduced from these photoproduction experiments with a carbon target is $V_{\text{had}}(q_0) = -m^2 - m = -37 \pm 10 \pm 10$ MeV and $W(q_0) = -10 \pm 2.5$ MeV at nuclear matter density $\rho_0$. This mass shift is very close to the prediction of the Quark Meson Coupling mode (QMC) [26], which also predicts a potential depth about $-100$ MeV for the $\eta'$ at $\rho_0$. The $\eta'$ results are also consistent with scattering length estimates from COSY-11 [27] and Bonn [28]. Experimental
search for $\eta'$ - nucleus bound states has also been performed with results reported in Ref. [29].

Hints for possible $\eta$ helium bound states are inferred from the observation of strong interaction in the $\eta$ helium system. One finds a sharp rise in the cross section at threshold for $\eta$ production in both photoproduction from $^3$He [2,30] and in the proton-deuteron reaction $dp \rightarrow ^3$He$\eta$ [31]. These observations may hint at a reduced $\eta$ effective mass in the nuclear medium.

Previous bound state searches at COSY have been focused on the reaction $dd \rightarrow ^3$He$\eta$ [8,9]. Studies of the excitation function around the threshold for $dd \rightarrow ^4$He$\eta$ did not reveal a structure that could be interpreted as a narrow mesic nucleus. Upper limits for the total cross sections for bound state production and decay in the processes $dd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta^0$ and $dd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta\pi^-$ were deduced to be about 5 nb and 10 nb for the $n\eta^0$ and $p\eta^-$ channels respectively [9]. The bound state production cross sections for $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}}$ [32] are expected to be more than 20 times larger than for $dd \rightarrow (^4$He-$\eta$)$_{\text{bound}}$ [33].

In May 2014 the experiment searching for $\eta$ mesic $^3$He nuclei was performed at the COSY accelerator [34,35] in Jülich, Germany. The measurements were carried out using the WASA-at-COSY detector [36–40]. The mesic nuclei are supposed to be formed in proton-deuteron collisions. A ramped proton beam with beam momentum varying in the range from 1.426 to 1.635 GeV/c corresponding to $^3$He$\eta$ excess energy range from $-70$ to $30$ MeV and a pellet deuterium target [41] were used. The $^3$He-$\eta$ bound state was searched for in the $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta^0$ and $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta\pi^-$ decay channels. These channels that manifest the direct decay of $\eta$ bound in $^3$He nucleus have been investigated for the first time. The existence of the bound $^3$He-$\eta$ state would manifest itself as a maximum or interference pattern in the excitation function for both of the studied reactions below the $pd \rightarrow ^3$He$\eta$ reaction threshold.

For the normalization of the excitation functions, the integrated luminosity was determined as a function of the excess energy. The analysis is presented in the next section. Further on, the data selection and efficiency determination is described. The data analysis is followed by the interpretation of the achieved excitation functions in view of the possible signal from the $\eta$-mesic $^3$He.

2. Luminosity determination

Luminosity was determined based on the $pd \rightarrow ^3$He$\eta$ and $pd \rightarrow p\eta$ reactions. The $pd \rightarrow ^3$He$\eta$ reaction analysis allows one to estimate the integrated luminosity for $^3$He$\eta$ excess energy $Q_{^3\text{He}\eta}$ above zero. The $^3$He particles were registered in the forward detector [36] and identified using the $\Delta E - E$ method based on energy losses in scintillator layers (see Fig. 1).

![Reconstructable tracks](image1.png)

**Fig. 1.** 2-D histograms of energies deposited in the first layer of Forward Trigger Hodoscope (FT1H1) and the first layer of Forward Range Hodoscope (FR1H1) for all events with signal in Forward Proportional Chamber (FPC) (left panel) and events that were identified as $^3$He (right panel).

![Q_{^3\text{He}\eta}] in [20, 22.5] MeV](image2.png)

**Fig. 2.** $^3$He missing mass spectrum obtained from data for the excess energy range of $Q_{^3\text{He}\eta} \in [20.0; 22.5]$ MeV. The part of the spectrum that is considered to be background is shown with green colour and is fitted with a polynomial of fourth power (orange).

The count of events originating from this reaction was obtained based on the $^3$He missing mass spectra for each excess energy interval separately. An example spectrum is shown in Fig. 2. The reconstruction efficiency was calculated using Monte Carlo simulations taking into account the experimental data on cross sections and angular distributions [40,42–44].

The $pd \rightarrow p\eta$ reaction analysis allows one to determine the integrated luminosity for the whole beam momentum range. As far as the target overlapping by the beam is changing during the acceleration cycle, the integrated luminosity value can change depending on the beam momentum. The registration efficiency for the $pd \rightarrow p\eta$ reaction was obtained with dedicated Monte Carlo simulations described in Refs. [45,46]. The distribution of relative proton-neutron motion inside the target deuteron was calculated based on the parametrisation of the Paris potential [47]. Data on the proton-proton elastic scattering cross section and the angular distribution [48] were used for simulating the quasi-elastic scattering in the framework of the spectator model. The calculated cross section was multiplied by the factor 0.96 to take into account the shading effect [49]. It is worth noting that above the $\eta$ production threshold, the two estimates of luminosity are in agreement (based on the $pd \rightarrow p\eta$ and $pd \rightarrow ^3$He$\eta$ reactions [45]). The total integrated luminosity was determined to be $2446 \pm 3\text{(stat.)} \pm 66\text{(syst.)} \pm 4\text{(norm.)} \text{nb}^{-1}$ where the statistical, systematic and normalisation errors are indicated, respectively [45]. This is the largest statistics ever obtained for these experimental conditions.

3. The analysis of $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta\pi^+$ and $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta\pi^-$ reactions

As a first step, in order to establish the optimal selection criteria, Monte Carlo simulations for the $pd \rightarrow (^4$He-$\eta$)$_{\text{bound}} \rightarrow ^3$He$\eta\pi^+$ reactions...
and \(pd \rightarrow ^{3}\text{He}-\eta\) reactions were performed in the framework of the spectator model with the assumption of an isotropic distribution of bound \(\eta\) meson decay products in its rest frame. The momentum of the \(\eta\) meson was simulated using the recent model [14] in which the \(\text{He}-\eta\) relative momentum distribution was calculated by solving the Klein-Gordon equation assuming the potential of \(\eta\)-nucleus interaction based on Hiyama's density distribution in \(^{3}\text{He}\) [50–52].

For the \(pd \rightarrow ^{3}\text{He}-\eta\rightarrow ^{3}\text{He}2\gamma\) reaction analysis, the events containing a \(^{3}\text{He}\) track in the forward detector and at least two photons in the central detector were selected. If there were more than two photons, the pair with the invariant mass closest to the \(\eta\) mass corrected by \(Q_{\gamma}\) value was chosen. Then the restrictions on \(^{3}\text{He}\) missing mass, \(\gamma\cdot\gamma\) missing mass, and \(\gamma\cdot\gamma\) invariant mass were applied using selection ranges based on the simulated distributions [45]. The excitation function obtained for the \(pd \rightarrow ^{3}\text{He}2\gamma\) reaction is shown in the left panel of Fig. 3.

The signal from the bound state is expected for excess energies around or below zero. The increase of events above 10 MeV is due to the \(pd \rightarrow ^{3}\text{He}\eta\) reaction. It starts at 10 MeV because of a hole in the geometrical acceptance of the WASA-at-COSY detector (see Fig. 4).

For the \(pd \rightarrow ^{3}\text{He}-\eta\rightarrow ^{3}\text{He}6\gamma\) reaction analysis, the events containing a \(^{3}\text{He}\) track in the forward detector and at least six photons in the central detector were selected. For each combination forming three pairs, to identify the \(\eta \rightarrow 3\pi^{0} \rightarrow 6\gamma\) decay, the following quantity is calculated:

\[
D = \sum_{i=1}^{3} (m_{\gamma i (2-1)\gamma 2i} - m_{\pi^{0}})^2
\]

where \(m_{\gamma i (2-1)\gamma 2i}\) is the \(\gamma\) pair invariant mass and \(m_{\pi^{0}}\) is \(\pi^{0}\) mass. The combination of six photons that minimises \(D\) was chosen. Then analogous to the \(2\gamma\) case, the selection conditions on the \(^{3}\text{He}\) missing mass, \(6\gamma\) invariant mass, and \(6\gamma\) missing mass were applied based on the simulated distributions [45]. The excitation function obtained for the \(pd \rightarrow ^{3}\text{He}6\gamma\) reaction is shown in the right panel of Fig. 3.

The excitation curves have been normalised using the integrated luminosity values calculated based on the \(pd \rightarrow ppn\) reaction and the efficiency determined based on Monte Carlo simulations. The results for both studied reactions are shown in Fig. 5.
4. The upper limit for the $\eta$ mesic $^3$He production cross section

The excitation curves obtained in the analysis (Fig. 5) did not reveal any resonance-like structures and the fit with linear functions results in $\chi^2$ value < 1 when normalized to the number of degrees of freedom. This indicates that no strong signal from the bound $^3$He-$\eta$ state is observed.

Further on, for the quantitative estimates of the upper limits for the bound state production, a fit to the excitation curves with a linear function (for background) plus a Breit-Wigner function (for the signal) was performed. The fit was done for different combinations of the assumed $\eta$-mesic $^3$He binding energies $B_\eta$ and widths $\Gamma$. The value of $\Gamma$ was tested in the range from 1.25 MeV to 38.75 MeV (with the step of 2.5 MeV) and $B_\eta$ in the range from 1.25 MeV to 63.75 MeV (with the step of 2.5 MeV).

For a given $B_\eta$ and $\Gamma$ pair, the following functions were fit simultaneously for the two studied reaction channels:

$$\rho_{^3\text{He}2\gamma}(Q_{^3\text{He}p}) = p_{\eta \rightarrow 2\gamma} \cdot \sigma_b(Q_{^3\text{He}p}) + p_1 Q_{^3\text{He}p} + p_2,$$

$$\rho_{^3\text{He}6\gamma}(Q_{^3\text{He}p}) = p_{\eta \rightarrow 6\gamma} \cdot \sigma_b(Q_{^3\text{He}p}) + p_3 Q_{^3\text{He}p} + p_4.$$

(2)

(3)

Here $\sigma_b$, $p_1$, $p_2$, $p_3$, and $p_4$ are the free fit parameters, $p_{\eta \rightarrow 2\gamma}$ and $p_{\eta \rightarrow 6\gamma}$ are the branching ratios for the $\eta \rightarrow 2\gamma$ and $\eta \rightarrow 6\gamma$ decays. Assuming that the ratio of branching ratios for the $\eta \rightarrow 2\gamma$ and $\eta \rightarrow 3\pi^0$ decay channels for the bound $\eta$ meson remain the same as in vacuum, the vacuum branching ratios of $p_{\eta \rightarrow 2\gamma} = 0.3941$ and $p_{\eta \rightarrow 3\pi^0} = 0.3268$ were used for performing the fit [12]. The function $\sigma_b(Q_{^3\text{He}p})$ in the fit formula represents a Breit-Wigner shape which for a given values of $B_\eta$ and $\Gamma$ reads:

$$\sigma_b(Q_{^3\text{He}p}, B_\eta, \Gamma) = \frac{\Gamma^2}{4} \left( \frac{Q_{^3\text{He}p}}{Q_{^3\text{He}p} - B_\eta} \right)^2 + \frac{\Gamma^2}{4}.$$

(4)

Example results of the fit are shown in Fig. 6. The figure shows results for the $B_\eta$ and $\Gamma$ values (indicated above the plots) for which the fitted values of $\sigma$ differ from zero with the largest statistical significance. Fig. 7 indicates the results of the fit as a function of the $B_\eta$ for the most promising value of $\Gamma = 28.75$ MeV.

The upper limit of the total cross section was determined based on the fit parameter uncertainty $\Delta \sigma_{\text{stat}}$:

$$\sigma_{\text{upper}}(B_\eta, \Gamma) = \sigma + k \Delta \sigma_{\text{stat}},$$

(5)

where $k$ is the statistical factor equal to 1.64 corresponding to 90% confidence level as given in PDG [12]. Fig. 7 shows the systematic limits (blue lines) in addition to the statistical uncertainties (green lines). Systematic errors were estimated by changing the parameters of all cuts applied in the data analysis, and changing the values of assumed potential parameters for the $^3$He-$\eta$ interaction that determines the Fermi momentum distribution for relative motion in the bound state. The highest contribution to the systematic error is connected with the background fit function. The uncertainty due to the fit of quadratic or linear function estimated as $\sigma_{\text{quad}} - \sigma_{\text{lin}}$ varies from about 2 to 5 nb.

In the obtained excitation functions one can see a slight signal from the possible bound state for $\Gamma > 20$ MeV and $B_\eta \in [0; 15]$ MeV corresponding to the optical potential parameters $-100 < V_0 < -70$ MeV and $|W_0| > 20$ MeV in the model described in [14]. The result is also consistent with the QMC prediction of a potential depth about $-100$ MeV at nuclear matter density [13] and with the models in Refs. [19,20,22,23]. The allowed $V_0-W_0$ area is however different to those deduced from the $^3$He system [54] using the optical model of Ikeno et al. [53] where most of the model parameter space was excluded allowing values of the real and imaginary parts of the potential only between zero and about $-60$ MeV and $-7$ MeV respectively. However, the observed signal is within the range of the systematic uncertainty. Hence one cannot make definite conclusions whether $\eta$-mesic $^3$He exists with the decay mechanism studied here.

5. Conclusions

The analysis of the $pd \rightarrow ^3\text{He}2\gamma$ and $pd \rightarrow ^3\text{He}6\gamma$ reactions has been performed in order to search for the existence of an $\eta$-mesic $^3$He state. The analysis of the obtained excitation functions for the $pd \rightarrow ^3\text{He}2\gamma$ and $pd \rightarrow ^3\text{He}6\gamma$ reactions shows slight indication of the signal from the bound state for $\Gamma > 20$ MeV and...
$B_\eta \in [0; 15]$ MeV. However, the observed indication is within the range of the systematic error which does not allow one to make a definitive conclusion on a possible bound state formation.

The upper limit for the cross section of the bound state production varies between 2 and 15 nb depending on the bound state parameters. It is however important to stress that the determined upper limit concerns the production of the $(^3\text{He}-\eta)^{\text{bound}}$ state and its subsequent disintegration via decay of the $\eta$ meson. The branching ratio for the latter in the nuclear medium remains to be estimated theoretically.

This is the first result obtained for the direct decay of bound $\eta$ meson. The upper limit is much lower than the limit of 70 nb for $pd \rightarrow (^3\text{He}-\eta)^{\text{bound}} \rightarrow ^3\text{He}\pi^-$ reaction obtained by the COSY-11 Collaboration [55] and is comparable with the upper limits obtained for the $dd \rightarrow (^3\text{He}-\eta)^{\text{bound}} \rightarrow ^3\text{He}\eta\pi^0$ and $dd \rightarrow (^4\text{He}-\eta)^{\text{bound}} \rightarrow ^3\text{He}\eta\pi^-$ reactions [9]. The much improved constraint will help tuning theoretical modelling of the $\eta$-nucleon and $\eta$-nucleus interactions.
